The recent report on laser cooling of liquid may contradict the law of energy conservation.

Laser cooling of liquid has recently been reported by Roder *et. al.*[1], however, such a cooling process is unlikely to happen since it violets the law of energy conservation.

The main result of the PNAS paper could be summarized as the following. A laser beam cools a YLF nanocrystal (which is immersed in a liquid) 20 degrees below the room temperature, which then cools the liquid surrounding it. The wavelength of the laser is $\sim 1020\text{nm}$, the irradiance on the sample is $\sim 25\text{MW}/\text{cm}^2$, the diameter of the YLF nanocrystal (10%Yb) is $\sim 1\mu\text{m}$, and the size of the cooled region of liquid is $\sim 5\mu\text{m}$.

This result may contradict the law of energy conservation, as the cooling power is much less than the thermal conduction power if there is really a temperature gradient around the nanocrystal.

Since the absorption length of the YLF crystal is about a few centi-meters[2], less than 0.01% of the incoming light power could be

absorbed by the nanocrystal (whose size is about $1\mu\text{m}$). The incoming light power on the sample is about $25\text{MW}/\text{cm}^2 \times (1\mu\text{m})^2 = 250\text{mW}$. The cooling power is at most $250\text{mW} \times 0.01\% \times 5\% = 1.3\mu\text{W}$, where 250mW is the incoming light power, 0.01% is the efficiency of the absorption, $5\% = (1 - 1000/1020)$ is the theoretical efficiency of the cooling process (the anti-stokes process). Recap it, the cooling power is at most $1.3\mu\text{W}$ [3]. Here we have not yet taken into account the rare probability of the anti-stokes process, which could be much less than 1% .

However, the thermal conduction power (heating power) of the surrounding liquid (say, water) is much more than that. Consider a water drop of $5\mu\text{m}$ radius around the nanocrystal. The heating power would be $6\text{mW}/\text{cm}\cdot\text{deg} \times 20\text{deg}/5\mu\text{m} \times 4\pi \times (5\mu\text{m})^2 = 750\mu\text{W}$, where $6\text{mW}/\text{cm}\cdot\text{deg}$ is the thermal conductivity of water, $20\text{deg}/5\mu\text{m}$ is the temperature gradient, and $4\pi \times (5\mu\text{m})^2$ is the area of the water sphere.

The estimation above is rough but it should not be far away from the reality. Since the heating power ($750\mu\text{W}$) is much more than the cooling power ($1.3\mu\text{W}$), it is unlikely for any cooling process to happen at all. In fact, with the thermal conduction of the surrounding water in mind, it is more likely for the nanocrystal to keep its temperature around the equilibrium (say, ± 1 degree), neither above nor below.

It may be worth noting that most of the earlier experiments in laser cooling of solids[4] should be checked for similar issues.

Y. J. thanks Prof. Pauzauskie for clarifying some issues in his paper. Y. J. acknowledges partial support from the NSFC (Grant No. 91321310) and the NBRPC (Grant No. 2013CB922304).

[2] as inferred from Melgaard et. al., “Optical refrigeration to 119 K, below National Institute of Standards and Technology cryogenic temperature”. Melgaard S. D., Seletskiy D. V. , Di Lieto A., Tonelli M., Sheik-Bahae M., Opt. Lett. **38**(9), 1588–1590(2013). The doping density of Yb in their YLF sample is 5% instead of 10%. The pump laser passes through the 1.2cm-long sample in 5 round-trips.

[3] The supplementary materials of the paper[1] give the number of Yb atoms in 1 m^3 , which is $n_{\text{Yb}} = 0.1 \times n_t = 1.4 \times 10^{27} \text{ m}^{-3}$. For a $1 \mu\text{m}$ -diameter sphere, there are only 1×10^9 Yb atoms. With the 1 mili-second lifetime of the natural radiation process, we may also reach the conclusion that the absorbed power is about $10 \mu\text{W}$.
